ABSTRACT

We present a detailed analysis of high-resolution *Chandra* observations of the merger system NGC3256, the most IR luminous galaxy in the nearby universe. The X-ray data show that several discrete sources embedded in complex diffuse emission contribute 20% of the total emission ($L_{\text{x}}^{\text{tot}} \sim 8 \times 10^{41}$ ergs s⁻¹ in the 0.5–10 keV energy range). The compact sources are hard and extremely bright and their emission is probably dominated by accretion driven processes. Both galaxy nuclei are detected with $L_{\text{x}} \sim 3 - 10 \times 10^{40}$ ergs s⁻¹. No evidence is found for the presence of an active nucleus in the southern nucleus, contrary to previous speculation. Once the discrete sources are removed, the diffuse component has a soft spectrum which can be modelled by the superposition of 3 thermal plasma components with temperatures $kT = 0.6, 0.9$ and 3.9 keV. Alternatively, the latter component can be described as a power-law with index $\Gamma \sim 3$. Some evidence is found for a radial gradient of the amount of absorption and temperature of the diffuse component. We compare the X-ray emission with optical, H α and NICMOS images of NGC3256 and find a good correlation between the inferred optical/near-IR and X-ray extinctions. Although Inverse Compton scattering could be important in explaining the hard X-rays seen in the compact sources associated with the nuclei, the observed diffuse emission is probably of thermal origin. The observed X-ray characteristics support a scenario in which the powerful X-ray emission is driven solely by the current episode of star formation.

Key words: galaxies: general – galaxies: active – galaxies: nuclei – X-rays: galaxies.

1 INTRODUCTION

The IRAS all-sky survey revealed a class of galaxies with infrared luminosities which overlap the bolometric luminosity of quasars. The vast amounts of energy released by these Luminous Infra-Red Galaxies (LIRGs: $L_{\text{IR}} > 10^{11} L$) and Ultra Luminous Infra-Red Galaxies (ULIRGs: $L_{\text{IR}} > 10^{12} L$) opened a question that has still not been completely resolved: what is the primary source of their power? The two favored answers are extreme starburst activity or the presence of an active nucleus. Important clues came from the observed correlation between IR luminosity and the presence of an AGN, showing that the fraction of Seyfert nuclei detected in optical surveys increases from $\sim 5\%$ to $\sim 50\%$

for objects with $\log L_{\text{IR}} \sim 10.5$ and $\log L_{\text{IR}} \sim 12.5$ respectively (Sanders & Mirabel 1996).

The definite presence (or absence) of an AGN in infrared luminous systems is difficult to test, since tens or even hundreds of magnitudes of visual extinction are routinely derived for the central regions of these galaxies. However, recent results from mid-IR observations using *ISO*, which can probe regions with extinctions as high as $A_V \sim 50$ magnitudes, show that 70 – 80% percent of ULIRGS are predominantly powered by star formation activity (Genzel et al 1998; Lutz, Veilleux & Genzel 1999).

Since nearly all ULIRGS have distorted morphologies it has been suggested that galactic interactions displace large masses of molecular gas into the central few kpc of these

Figure 1. *Chandra* images of NGC3256 in the 0.3-1.5 (left) and 1.5-10 (right) keV energy ranges. The images extend ~ 60 arcsecs on each side. North is at the top and East is on the left. Discrete sources are labelled by increasing order of right ascension. Sources 1 and 14 are not included in the figure (see Table 1 for celestial coordinates).

systems, fueling a powerful starburst or an accretion powered AGN. Several possible evolutionary scenarios have been proposed to link ULIRGs with QSOs, ‘super-starbursts’ and elliptical galaxies (Sanders et al 1988; Joseph & Wright 1985; see also L  pari et al 2001 and references therein).

NGC3256 is a spectacular merger system. Its IR luminosity of $6 \times 10^{11} L$ makes it the most luminous object in the local ($z < 0.01$) universe^{*}. Evidence of a recent interaction is the presence of 200 kpc extended tails and a highly chaotic nuclear region (Graham et al 1984). Direct evidence for the presence of a powerful starburst in the galaxy comes from the detection of strong absorption features from massive stars (Doyon, Joseph & Wright 1994, L  pari et al 2000). The central region of the starburst (~ 5 kpc across) is characterized by strong near-IR line emission, high metallicities, and outflows. (Moorwood & Oliva 1994; L  pari et al 2000). A double nucleus has been detected at radio and near-IR frequencies (Norris & Forbes 1995; Kotilainen et al 1996), suggesting that NGC3256 is not a very advanced merger system. While the northern nucleus has always been recognised as a pure starburst, the presence of a hidden AGN in the southern nucleus has remained a matter of speculation.

X-ray observations of NGC3256 were obtained previously with *ROSAT* and *ASCA*. From the analysis of *ASCA* data Moran, Lehnert & Helfand (1999, hereafter MLH) determined a total luminosity in the 0.5-10 keV energy range of 1.6×10^{42} ergs s⁻¹. If powered solely by star formation, NGC3256 would represent the top end of the X-ray luminosity distribution of starburst galaxies. MLH also argued that the observed power law tail could not be explained by the presence of an AGN or a population of Galactic-type X-ray binaries and suggested that Inverse Compton scattering could provide a substantial fraction of the observed high energy component.

In order to understand the nature of the NGC3256 powerful emission, observations at high spatial resolution are required. High resolution X-ray observations are particularly suited for this aim, since hard X-rays are able to probe deep into the most obscured regions and give vital information about hot gaseous components commonly associated with strong starbursts and which are undetectable at other wavelengths. In this paper we report recent high resolution observations of NGC3256 made using the *Chandra* X-ray Observatory. This paper is organised as follows: section 2 gives details of the data analysis procedure while sections 3 and 4 focus on the characteristics of the population of compact sources and the diffuse emission respectively; in section 5 a brief comparison between the *Chandra* and *ASCA* observations is given; a full discussion is presented in section 6 and conclusions and summary can be found in section 7.

Table 1. Detected discrete sources in NGC3256. Background subtracted source counts (*SC*) above 0.3 keV are given for each source. The significance of the detections was determined as SC/σ_B , where σ_B is the standard deviation of the background and was computed as $1 + \sqrt{\text{Background counts} + 0.75}$. This correction to the standard deviation gives a more appropriate estimate of Poissonian errors for cases of low number counts (Gehrels 1986).

2 OBSERVATIONS AND DATA ANALYSIS

A *Chandra* 28 ks observation of NGC3256 was obtained on the 5th of January 2000. For an assumed distance of 56 Mpc, 1 arcsec (encircling $\sim 90\%$ of the photons from a point source at 1.5 keV[†]) corresponds to a linear size of 270 pc. The data were analysed using a combination of *Chandra* X-ray Center (CXC) Ciao (V1) and HERSARC XSPEC (V10.0) software. The galaxy was imaged using the (back-illuminated) ACIS S3 chip, which is known to suffer from flares of high background radiation. An examination of our observations, after discarding all events outside the 0.3-10.0 keV energy range, showed that in fact about half of the observing time was affected by high background. The strategy adopted to ensure minimum contamination from the high background episodes is described in sections 3 and 4.1. The average count rate during the observation was found to be 2.55 counts per second in the S3 chip, compared with the quiescent 0.79 counts per second measured in-flight[‡]. The three known bad columns of the S3 chip were located far away (~ 5 arcmin) from our target and therefore did not induce any problems during the data analysis.

Simple aperture photometry shows that all the galactic emission is contained within a circle of radius ~ 60 arcsec, while circles of radius ~ 27 and ~ 18 arcsec encircle $\sim 95\%$

^{*} A distance of 56 Mpc ($z = 0.009$, $H_0 = 50$ km s⁻¹ Mpc⁻¹) has been used throughout this paper.

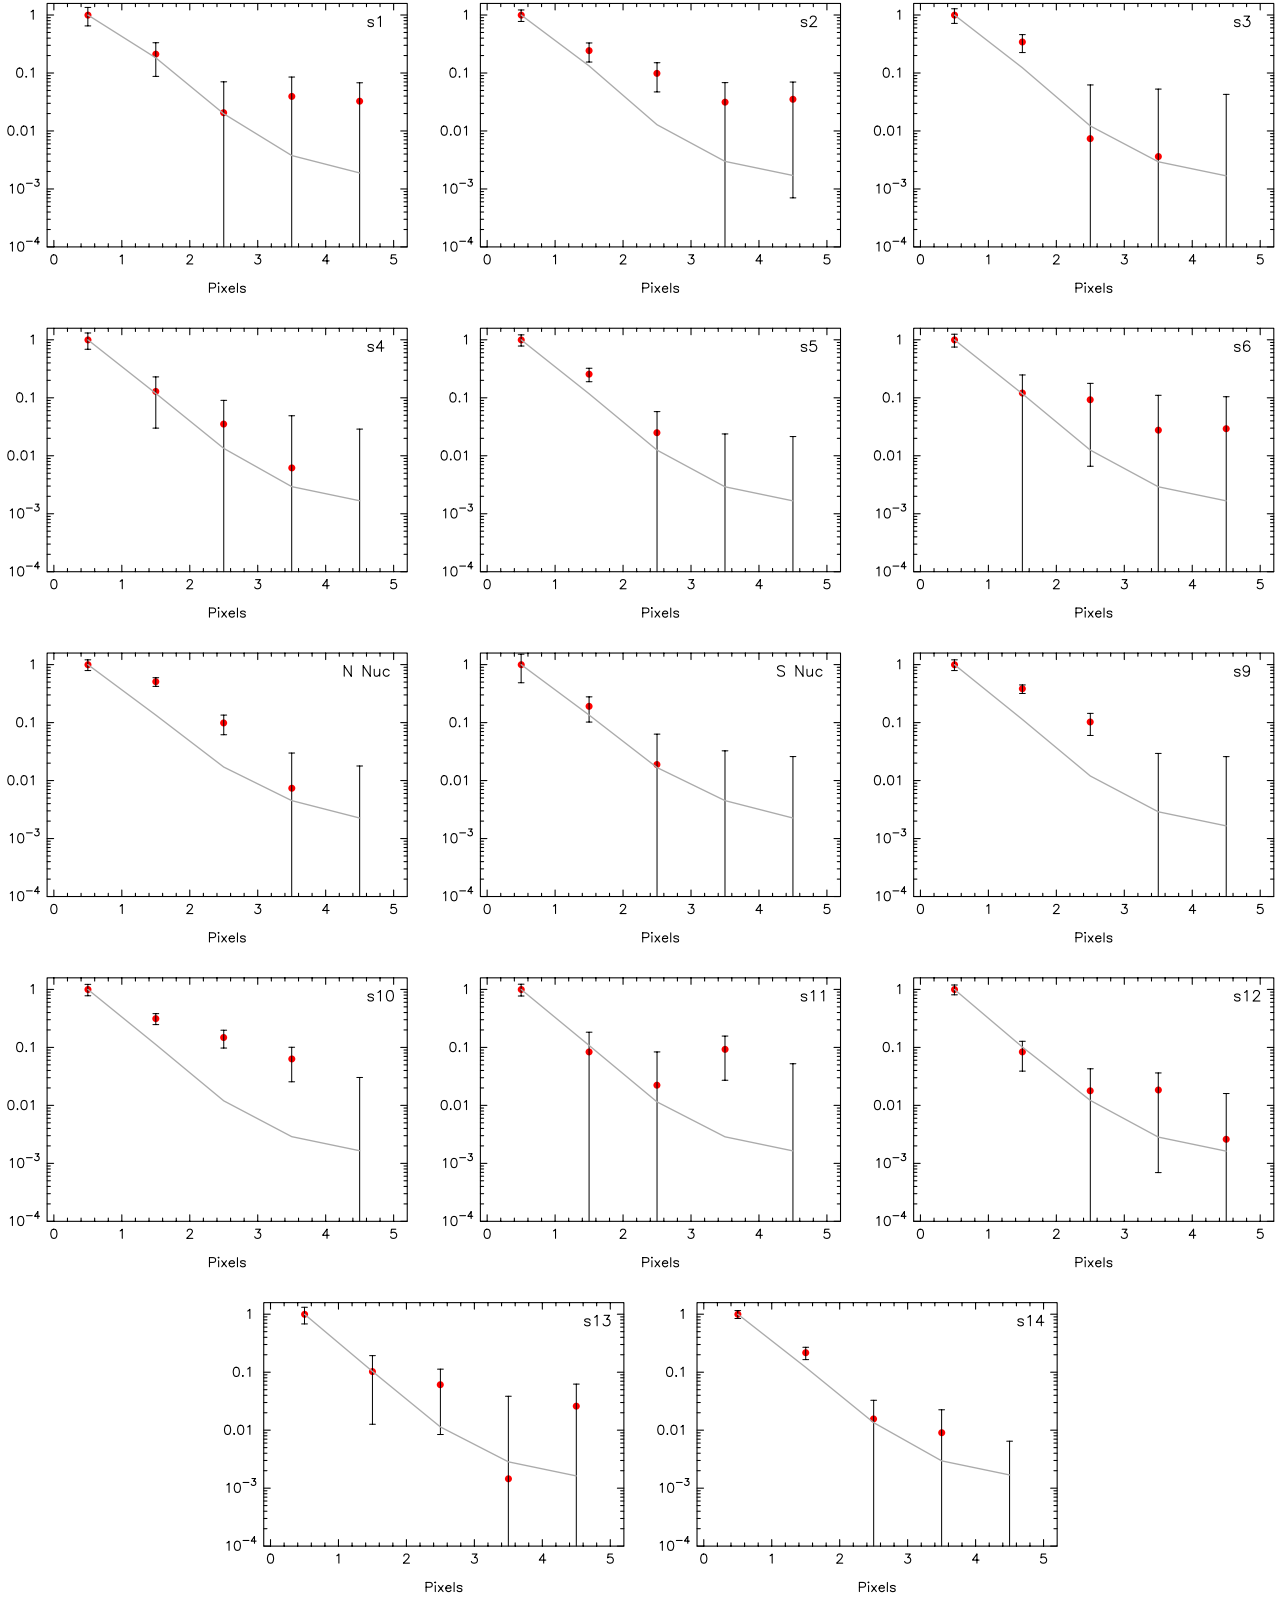

Figure 2. Spatial profiles of the discrete sources obtained from a full 0.3-10 keV band image and compared with the model PSF (continuous lines). The error bars correspond to 1σ confidence levels. The profiles for both nuclei (N and S) were obtained from a harder, 2-5 keV image.

and $\sim 90\%$ of the counts, respectively. The large first radius is necessary to contain the two most distant discrete sources (sources 1 and 14 in Figure 1 and Table 1), which are located at $\sim 40 - 55$ arcsec from the central peak of emission.

Due to a calibration error in early *Chandra* data, the astrometry of the original observations of NGC3256 were affected by a ~ 8 arcsec shift in absolute astrometry. After reprocessing of the data at the CXC, which corrected for this problem, we found that the position of the brightest X-ray compact source seen in the galaxy (source 7 in Figure 1 and Table 1) was offset with respect to the radio position for the northern nucleus (which is coincident, within 1 arcsec, with the position of the nucleus seen at optical and IR wavelengths - Norris & Forbes 1995) by only 0.44 arcsecs. Also, good positional agreement is found between several knots of emission seen in X-rays and optical wavelengths (see sections 6.2 and 6.3.1).

Figure 1 shows a $\sim 60 \times 60$ arcsec *Chandra* image of NGC3256 in the 0.3-1.5 and 1.5-10 keV energy ranges. The soft image shows a significant and spatially complex diffuse component. Several of the discrete sources are more easily seen in the harder band, where the diffuse emission has a much lower surface brightness. The emission is dominated by a strong compact source located at the center of the X-ray emitting region and labeled as source 7. As mentioned above, this source has been identified with the northern nucleus of the galaxy. Another, harder source is found 5 arcseconds to the south of this position in the 1.5-10 keV band (source 8), and is identified as the X-ray counterpart of the southern nucleus. The diffuse emission shows complex morphology, with a strong central ‘Bar’ running in a ES to NW direction just above of the northern nucleus. Another interesting feature is a southern ‘Arm’ connecting sources 8 and 2, which leaves a void of soft X-ray emission at the position of the southern nucleus.

3 DISCRETE SOURCES

A wavelet detection algorithm was used to search for compact sources associated with NGC3256. This algorithm is particularly suited for the detection of closely spaced and extended sources. However, given the strong and complex extended emission component in the central region of NGC3256, it still is possible that strong fluctuations of the background can be identified as spurious sources. For this reason, the detection algorithm was run using an image in the 1.5-10 KeV energy range only, where discrete sources are more conspicuous. Also, low surface brightness and obviously extended sources in the Arm and to the NW of the bright central source were disregarded since their morphology did not appear less smeared in the hard band image. The final source list was compiled only after the determination of the detection significance for each source. A total of 14 compact sources were found with a detection significance ($= (\text{source counts}) / (\text{background standard deviation})$) ranging from ~ 140 to ~ 12 (see Table 1). The sources are shown in Figure 1 and labeled from 1 to 14 with increasing right ascension.

For each discrete source a background subtracted number of counts was obtained from within a $r = 3.5$ pixel aperture (1.72 arcsec). This encircles $\sim 99\%$ of the photons at 0.3

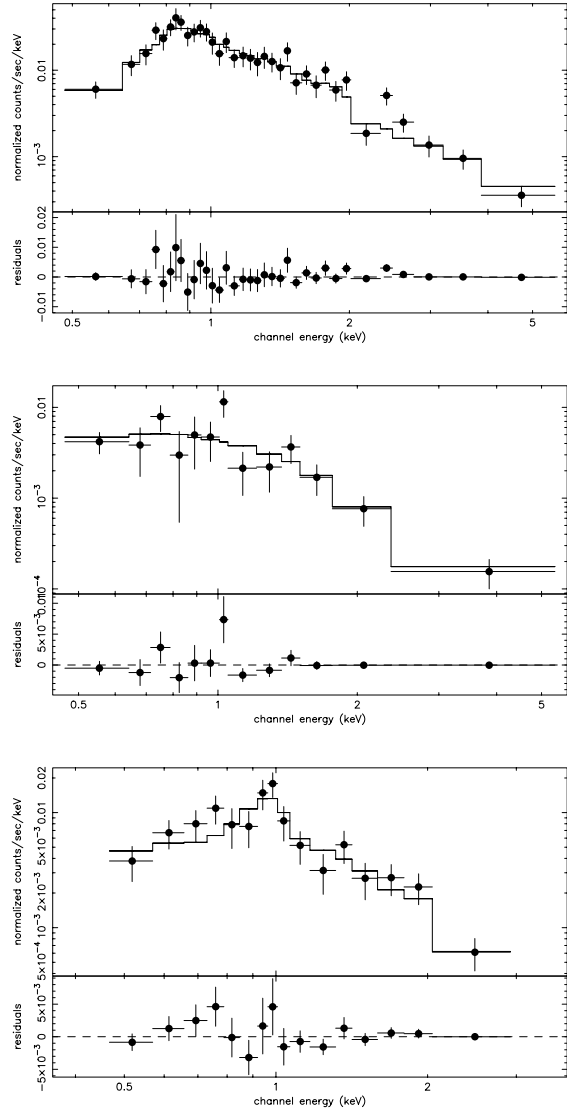

Figure 3. Spectra of the 3 brightest discrete sources in NGC3256 in the 0.5-10 keV range: source 7 (the Northern nucleus - top), 9 (centre) and 10 (bottom). The top panels of each plot show the data and folded model (see Table 2). The bottom panels show the residuals to the fit.

keV and $\sim 90\%$ of the photons at 5.0 keV (in general, sources were not detected above this energy). The small apertures used imply that on average only ~ 2 of the source counts are expected to correspond to the background. Therefore, the study of these sources was done without screening out the high background episodes. None of the sources was affected by pileup. For each individual source a local background region was defined by using an annulus with $r \sim 5 - 10$ pixels centered at the position of the source with holes excised at the position of any other nearby compact sources. The determined counts and associated significance can be found in Table 1.

3.1 Spatial Analysis

We have analysed the spatial profile of the detected sources. To do this we obtained locally background subtracted counts

Table 2. Fitted models for the emission from sources 7 (the northern nucleus), 9 and 10. Hydrogen columns are given in units of 10^{21} cm^{-2} and plasma temperatures in units of keV. The errors correspond to 90% CL for 1 parameter of interest. *Observed* fluxes are in units of 10^{-14} $\text{ergs s}^{-1} \text{cm}^{-2}$ and *intrinsic* luminosities are in units of 10^{40} ergs s^{-1} (for an assumed distance of 56 Mpc).

†: Same hydrogen column as applied to previous spectral component.

Throughout this paper, whenever the column of gas fitted to a low temperature thermal component (probably associated to a large-scale extended hot phase) presented an unrealistically low value of N_H , the Galactic hydrogen column ($N_{\text{Gal}} \sim 9 \times 10^{20} \text{ cm}^{-2}$, labelled as *Gal*) was adopted instead.

within circular apertures of radius 1, 2, 3, 4 and 5 pixels and compared them with model PSFs generated at the position of each source (Figure 2). The full 0.3-10 keV band image was used to obtain the source profiles, except for both nuclei, for which a harder 2-5 keV band image was used. In this way the amount of diffuse emission around the northern nucleus was minimised, and the detectability of the obscured southern nucleus was maximised. The major difficulties in obtaining a meaningful analysis of the profiles are the poor sampling of the PSF (at 1.5 keV, for example, $\sim 90\%$ of the energy is expected to fall within only 4 pixels), and the presence of the strong and spatially variable diffuse component.

For isolated sources, such as sources 1, 4, 5, 12, 13 and 14, the photometry suffers little from contamination by extended emission and therefore the profiles are reliable despite the small number of counts detected for some of the sources. All sources show profiles consistent with the model PSF, although source 5 shows some evidence for an extended component. However, as this is based on only one data point, we will assume that all isolated sources are indeed unresolved.

The scenario is less straightforward for those sources located in the innermost region of the galaxy since the background estimates will not account for any spatial changes of the diffuse emission within the apertures used to obtain the profiles. Figure 2 shows that while the spatial distribution of sources 3, 6, and 8 (the southern nucleus) 11 and 13 are well described by the model PSF, sources 2, and 7 (the northern nucleus) 9 and 10 are clearly resolved.

A simple Gaussian fit to the profiles shown in Figure 2 gives FWHM values (the only parameter allowed to vary during the fitting) of $\sim 0.8 - 1.5$ pixels ($\sim 0.4 - 0.7$ arcsec) for unresolved sources, while extended sources had FWHM $\sim 2.2 - 2.8$ pixels (implying deconvolved FWHM $\sim 1.8 - 2.5$ pixels or $\sim 0.9 - 1.3$ arcsec). The model PSF had a FWHM ~ 1.2 pixels (~ 0.6 arcsec). The only source that did not follow this trend was source 2, which has a best fit value of 1.5 pixels (ie, within the range of the unresolved sources), even though Figure 2 suggests that the profile is extended.

The aperture used to perform the count subtraction ($r = 3.5$ pixels) is only adequate if it contains most of the flux from the extended sources. The Gaussian fit to the profiles shows that these sources have a FWHM of up to 2.8 pixels (ie, $3\sigma = 3.6$ pixels or ~ 1.8 arcsecs). A well centred extraction aperture of 3.5 pixels, therefore, will contain most of the source counts. Since all extended sources show a well defined peak, and sources 7, 9 and 10 correspond to the brightest discrete sources found in the galaxy, the centering of their flux distribution is well determined and, therefore, these apertures were adequate.

3.2 Fluxes and luminosities

Only three of the 14 detected discrete sources had sufficiently high numbers of counts to perform a useful spectral analysis. These correspond to source 7, the northern nucleus, and sources 9 and 10. The spectra were modeled with a single (Mekal (M) or power-law (PL)) component and a double (Mekal and power-law (M+PL) model in the 0.5-10 keV band pass. These models are representative of sources dominated by thermal emission (such as SNRs and galactic bubbles), non-thermal emission (such as accreting compact objects), and composite objects.

For all sources the single Mekal model was a very poor representation of the data, while the single power-law gave a much better fit, particularly for source 9, given the low number of bins available (see Table 2 and Figure 3). For sources 7 and 10, M+PL models were also tried. For source 7 two independent hydrogen columns were adopted for each spectral component in model *c*. This model represents a physically plausible scenario with the low temperature Mekal component representing a large-scale extended gaseous phase, and the harder, more absorbed component arising from embedded or intrinsically absorbed sources directly associated with the northern nucleus. Since the best fit values of the hydrogen column affecting the low temperature Mekal component were very close to or slightly less than Galactic, we fixed the N_H to the Galactic column (see note-foot in Table 2),

Figure 4. ‘Hardness-ratios’ (colour-colour) diagram for X-ray discrete sources. The X-ray colours were defined as the ratio of counts observed in the 0.3–1.0 keV, 1.0–2.0 keV and 2.0–7.0 keV energy bands. One σ error bars are shown. The grids of models correspond to single Raymond-Smith plasmas (triangles - dash-dotted line) with temperatures (from top to bottom) 6.0, 3.0, 1.0 and 0.5 keV, and single power laws (squares - dotted line) with index Γ (from top to bottom) 0.5, 1.0, 1.5, 2.0, 2.5 and 3.0. From right to left successive grids correspond to absorbing columns of 10^{21} (just above Galactic), 5×10^{21} and 10^{22} cm^{-2} respectively. Sources 7, 9 and 10, for which spectral fits were properly derived are also included.

resulting in the same number of degrees of freedom as model *b*.

To convert the count rates to fluxes for the remaining sources we must assume an intrinsic spectral shape and intervening absorbing column. In order to gain some insight into the best values to adopt, we studied the X-ray colours of the sources, defined as the ratio of counts observed in the 0.3–1.0 keV, 1.0–2.0 keV and 2.0–7.0 keV energy bands. The bands were chosen in order to maximise the detection of the sources in all three bands, as well as to obtain a good characterization of the spectra. To compare the observed X-ray colours of the sources with different spectral shapes, we computed the colours of pure power-law and Raymond Smith models using the HEASRAC Portable, Interactive, Multi-Mission Simulator (PIMMS - Mukai 1993).

Grids of points were determined for parameters $\Gamma = 0.5 - 3.0$ and $kT = 6.0 - 0.5 \text{ keV}$, for the power-law and Raymond Smith models respectively, and for $N_H = 10^{21} - 10^{23} \text{ cm}^{-2}$. In figure 4 we have plotted the computed grids along with the observed colours of the discrete sources. Error bars were computed as 1 standard deviation in the count ratios. The southern nucleus (source 8) is not shown since it is not detected in either of the two softest bands used in the diagram (see further discussion below in this section).

The positions for sources 7, 9 and 10 can be used to investigate the limitations in using these type of diagrams, since we have determined their spectral parameters from spectral fits. From the single power-law fits showed in Table 2 we find that all sources have an absorbing column higher than Galactic but lower than $5 \times 10^{21} \text{ cm}^{-2}$, in agreement

with the location of the sources in the colour-colour diagram. However, from the diagram the columns are underestimated for sources 7 and 10. For source 7 for example, $N_H \sim 4 \times 10^{21} \text{ cm}^{-2}$ is found from the spectral fit, while the column deduced from the colour-colour diagram is about 10^{21} cm^{-2} . The fitted power-law indices also roughly agree with the location of sources 9 and 10, giving values of $\Gamma \sim 2.5 - 3.0$. A larger discrepancy is seen for source 7 where the power-law index estimated from the diagram is harder ($\Gamma \sim 2.0 - 2.5$) than its fitted value. These disagreements could be due to the observed spectral complexity of the emission in source 7 which cannot be recovered by the over-simplified single parameter models used in the colour-colour diagram. For source 9, however, the only case where the single power-law model gives an acceptable fit ($\chi^2_{\text{red}} \sim 1.0$), the best fit values suggest a hard source and a moderate hydrogen column ($\Gamma \sim 2.4$, $N_H \sim 1.6 \times 10^{21} \text{ cm}^{-2}$), which is not accurately reflected by the position of the source in the colour-colour diagram. These comparisons clearly illustrate the limits to using colour-colour and hardness-ratio diagrams.

The positions of the remaining sources in the colour-colour diagram show that most of the sources have an absorbing column above the Galactic value, ie between 10^{21} and $5 \times 10^{21} \text{ cm}^{-2}$. The bulk of the sources show a harder spectral shape than those for which we have performed a spectral fitting and therefore a power law with index between $\Gamma = 2.0$ and 2.5 seems a reasonable spectral shape to adopt. Bearing in mind the limitations in obtaining spectral parameters from the colour-colour diagram as discussed above, the derived power-law indices are in good agreement

Table 3. Fluxes and luminosities in the 0.5-10 keV energy range for the compact sources assuming a single power law component with index $\Gamma = 2.0$ and 2.5 . The adopted hydrogen columns are also given. *Observed* fluxes are in units of 10^{-14} ergs s^{-1} cm^{-2} and *intrinsic* luminosities are in units of 10^{40} ergs s^{-1} (for an assumed distance of 56 Mpc).

Source	N_H	$\Gamma = 2.0$		$\Gamma = 2.5$

Figure 5. Stacked spectra for heavily absorbed sources 2, 3 and 8 (triangles), and less absorbed sources 5, 6, 11 and 13 (circles).

with that expected from a population of high-mass X-ray binaries ($\Gamma \sim 1 - 2$ White, Nagase & Parmar, 1995) or young supernova remnants ($kT \sim 1 - 4$ keV, Bregman & Pildis 1992). Sources 2 and 3, however, do not follow the trend shown by the rest of the sources and present evidence for much larger absorption. These sources are not detected in the 0.3-1.0 keV band and we only have an upper limit for their (0.3-1.0 keV)/(1.0-2.0 keV) colour. A column density of 10^{22} cm^{-2} was chosen as a representative value for these two heavily absorbed sources.

In order to check that the range of power-law indices and absorbing columns inferred from the colour-colour diagram are representative of ‘real’ spectral shapes, we produced two ‘stacked’ spectra for a group of obscured and unobscured sources. The sources were selected based on their observed colours in Figure 4 and from their location with

Figure 6. Discrete source lightcurves. The average count rate for each source is plotted as a straight line.

respect to the reddening observed in a colour image of the central region of the galaxy (see section 6.2). Figure 5 clearly shows that although the observed hard tails present a similar slope for the two stacked spectra, the soft end shows clear evidence for significant absorption in these sources, in good agreement with their position in the colour-colour diagram. Single component models (M or PL) were fitted to the stacked data and showed that the absorbing column affecting the unobscured sources was a few times the Galactic value, while the corresponding value for the obscured sources was about an order of magnitude larger.

The southern nucleus is only detected at hard energies, and no counts are detected below ~ 2.0 keV. This is perhaps not surprising, since it is well established that this is a heavily obscured region. To characterise the spectral shape of this nucleus we have again used a colour-colour diagram, but this time using the 2.0-3.3 keV, 3.3-4.5 keV and 4.5-10 keV energy range. The bands were chosen in order to maximise the background subtracted number of counts in each one of them. We then compared the observed (2.0-3.3 keV)/(3.3-4.5 keV) and (4.5-10 keV)/(3.3-4.5 keV) colours with grids of power law models as described previously. We find that the spectral shape of the source is well parameterized by a range of indices $\Gamma \sim 1.0 - 2.5$ if an absorbing column of 5×10^{22} cm^{-2} is adopted. A higher column (10^{23} cm^{-2}) is possible but only if $\Gamma 2.0$, while a lower column (10^{22} cm^{-2}) requires $\Gamma 1.5$. Columns above 10^{23} cm^{-2} or below 10^{22} cm^{-2} are not consistent with the observed colours.

The final computed fluxes and luminosities for all sources are listed in Table 3. They were computed assuming a power law spectrum with indices $\Gamma = 2.0$ and 2.5 and the hydrogen columns discussed above. The adoption of the different indices implies changes in the fluxes of about $\sim 30\%$. Much larger errors could be introduced if the spectral shapes are not well described by the assumed models, as can be seen by comparing the fluxes and luminosities obtained for source 7 from the spectral fitting and the adopted parameters used in Table 3. Statistical errors will dominate, however, for the faintest sources (30 counts - see Table 1). Another significant source of uncertainty is the adoption of a representative background. This problem is particularly important for sources embedded in strong diffuse emission. In all, the fluxes and luminosities in Table 3 are probably good to within a factor of two or three. Inspection of Tables 1 and 3 shows that our sensitivity threshold is $\sim 4 \times 10^{-15}$ ergs s^{-1} cm^{-2} ($\sim 1.5 \times 10^{39}$ ergs s^{-1}) for an isolated source, and $\sim 1.5 \times 10^{-14}$ ergs s^{-1} cm^{-2} ($\sim 6 \times 10^{39}$ ergs s^{-1}) for sources embedded within the diffuse emission.

3.3 Time variability

In order to search for time variability of the discrete sources light curves for the 6 brightest objects were constructed using 6 bins of 4.3 ksec each, spanning a total of 26 ksecs. The errors associated with the count rates correspond to 1σ deviations assuming Poisson statistics. The light curves are shown in Figure 6.

Figure 7. Left: Spectrum of the diffuse component in NGC3256 in the 0.5-5 keV range. The top panel shows the data and folded model; the bottom panel shows the residuals in the same energy range. Right: best fit model components.

A superficial examination shows no obvious signs of variability in the lightcurves. We carried out a χ^2 test to compare the lightcurves with a constant distribution. The test showed that all distributions are consistent with no variability ($\chi^2_{\text{red}} 0.5$), except for source 6 where no variation is a poorer representation of the data ($\chi^2_{\text{red}} = 1.59$). However, this is not a significant result, and the null hypothesis is not rejected at the 85% confidence level.

4 DIFFUSE EMISSION

4.1 Integrated spectrum

In order to perform a spectral analysis of the diffuse component in NGC3256 a large aperture with a diameter of 40 arcsec (~ 11 kpc) was defined after removing all discrete sources. At this distance from the central peak of emission the diffuse emission had a comparable surface brightness to the background. The large aperture used implies that the observed episodes of high background described in Section 2 could contaminate the intrinsic emission from the galaxy. Therefore the data were filtered to exclude background count rates above 1.5 counts per second. Consequently only 14.5 ksec ($\sim 52\%$) of the total observing time was used. These screened data are used for all the analysis described here and in section 4.2.

The aperture was fully contained within only one (out of four) of the readout nodes of the S3 chip (node to node sensitivity changes can be as large 10 percent). In fact, the bulk of the extended component covered a roughly circular region with a diameter 30 arcseconds, compact enough for the response of the detector to remain fairly constant. For this reason only one set of Fits Embedded Functions (FEF - a FITS table which stores the mapping of the energy to pulse height) was used to calibrate the spectrum. (Using a response built up from the weighted combination of the 3 to 4 FEFs that fully covered the area subtended by the diffuse component did not change the fit to the data). The background was obtained from a large semi-annular region surrounding NGC3256 ($r \sim 75 - 115$ arcsec) and fully contained within the same readout node as the emission from the galaxy.

Figure 7 shows the spectrum of the diffuse emission. A

total of ~ 2860 counts were detected within the aperture, of which at most ~ 100 could be from the background. The relative softness of the emission is evident as no counts are detected above ~ 5 keV. The presence of strong emission lines is also readily visible at ~ 1.4 keV and ~ 1.8 keV. At these energies we expect contributions from lines such as He-like and K-shell emission of Mg and Si ions, indicating the presence of a thermal component with $kT < 2$ keV.

The spectrum of the diffuse emission was first fitted using single and double component models which yielded unacceptable chi-squared values. We then followed with three-component models (M+M+M or M+M+PL). The presence of multi-temperature gas has already been claimed for several starburst galaxies, such as NGC1808 (Awaki et al 1996), Arp 299 (Heckman et al 1999), NGC4449 (della Ceca, Griffiths & Heckman, 1997), NGC253 and M82 (Ptak et al 1997). The introduction of a power law component could account for an unresolved population of accreting binaries. Since different spectral components can have different degrees of absorption (see references above), we allowed for different N_H values for the fitted components. We also fixed the hydrogen column absorbing the softest thermal plasma component to the Galactic value, since fitting the parameter nearly always resulted in a Galactic or slightly under-Galactic value.

The results of the spectral fits are reported in Table 4. Solar metallicities were assumed throughout, consistent with the optically measured abundances (Lípari et al 2000). If left free to vary, the abundances imply a solar or over-solar value, without significantly improving the fit. For the first two models in Table 4, the second and third spectral components are subject to the same hydrogen column. For the third and fourth model, each component has an independent intervening N_H . Despite the clear improvement in the statistics of the successive models presented in Table 4, it was impossible to reduce χ^2_{red} below 1.3. This is probably due to the still preliminary status of the instrument responses available for the calibration of the data. The uncertainties mostly affect the modeling of line emission dominated spectra. All the models in Table 4 are consistent with a general picture of a moderately absorbed cool thermal plasma plus a warmer thermal component with a much higher absorption. A steep power law or a thermal component with a temperature of about 4 keV is necessary to explain the faint hard tail

Table 4. Best-fit model parameters for the diffuse emission in the 0.5-10 keV energy range. Solar abundances were assumed for the Mekeal components. Intervening hydrogen columns are in units of 10^{21} cm^{-2} and plasma temperatures are in units of keV. *Gal* stands for a foreground Galactic hydrogen column ($9 \times 10^{20} \text{ cm}^{-2}$). Errors correspond to 90% CL for one parameter of interest. *Observed* fluxes are in units of $10^{-13} \text{ ergs s}^{-1} \text{ cm}^{-2}$ and *intrinsic* luminosities are in units of $10^{41} \text{ ergs s}^{-1}$ (for an assumed distance of 56 Mpc).

Model	N_H	kT	N_H	kT	N_H	kT or Γ	$\chi^2_{\text{red}}(\text{dof})$	F_x	L_x
M+M+M	<i>Gal</i>	$0.37^{+0.04}_{-0.03}$	$7.1^{+1.1}_{-1.0}$	$0.76^{+0.04}_{-0.05}$	†	$2.76^{+1.90}_{-0.67}$	1.54(59)	6.78	8.32

† Same hydrogen column as applied to previous spectral component.

‡ The best fit value of N_H was found to be slightly under Galactic.

* Model component normalizations: 1.1×10^{-4} and 4.9×10^{-4} for the 0.6 and 0.9 keV Mekeal components respectively, in units of $(10^{-14}/(4\pi D^2)) \times \int n_e^2 dV$ (where D is the distance to NGC3256 in cm, n_e is the electron density in cm^{-3} , and V is the volume of the emitting region in cm^3); 1.5×10^{-4} for the Power Law, in units of $10^{-4} \text{ photons cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}$.

Table 5. Fluxes and luminosities for the diffuse emission in the 0.5-10 keV energy range from the M+M+PL model. *Observed* fluxes are in units of $10^{-14} \text{ ergs s}^{-1} \text{ cm}^{-2}$ and *intrinsic* luminosities are in units of $10^{41} \text{ ergs s}^{-1}$ (for an assumed distance of 56 Mpc).

Component	F_x	L_x	F_x	L_x
	0.5-2.5 (keV)	0.5-2.5 (keV)	2.5-10 (keV)	2.5-10 (keV)
Cool Mekeal	20.5	1.31	0.21	0.01
Warm Mekeal	17.2	3.83	3.07	0.13
Power Law	15.1	1.38	9.96	0.38
Total	52.8	6.26	13.2	0.52

seen in the spectrum. Table 5 lists fluxes and luminosities derived for each component from the model with the best reduced chi-squared (M+M+PL model; last entry in Table 4).

4.2 Spatially resolved spectra

The spectral-imaging capabilities of *Chandra* enable a more detailed study of the diffuse emission. Ideally, we would like to identify each of the spectral components determined in the previous section with a specific spatial region, but this is only possible if each component strongly dominates the local emission.

Two thermal components have been clearly identified in the *Chandra* data. Observational evidence on galactic winds suggests that the central regions of starbursts are characterised by higher plasma temperatures than the outer regions (Strickland, Ponman & Stevens 1997, Pietsch et al 2000). This is also supported by various theoretical models of galactic winds (Suchkov et al 1996, Chevalier & Clegg 1985). Given the nearly face-on orientation of NGC3256 we decided to extract spectra from annular regions centered in between both nuclei. After experimenting with different radii we defined three regions, A, B and C with outer radii of 15, 23

and 40 pixels ($\sim 4, 6$, and 11 kpc). This choice gives a similar number of counts ($\sim 900 - 1000$) in each region and also provides a good representation of the spectral changes with radius. Region C is roughly coincident (although with a larger outer radius) with the onset of a ring of broad H α line emission (FWZI up to 6000 km s^{-1}) probably associated with the wind, as discussed by MLH.

The regions are shown in Figure 8 overlaid onto a smoothed image of the X-ray emission. The spectra obtained for each region (after removing the discrete sources) are also shown. The spectra show that while the emission above 1 keV shows a similar trend for all radii, the dispersion is much larger below 1 keV, suggesting that different amounts absorption and/or peak temperatures may characterise the different regions.

In order to quantify the different spectral trends observed in Figure 8 we fitted each spectrum with a thermal plasma plus a power law (M+PL), each component absorbed by an independent hydrogen column. The power law component was fixed with an index of 2.7. The results are shown in Table 6. The best fitted value for the hydrogen column affecting the thermal plasma in region C was very close to Galactic and therefore, given that a column much larger than Galactic is unlikely to pertain across such an extended region, a value of *Gal* was adopted.

The results in Table 6 show a trend of the spectral parameters with radius. The most robust result concerns the amount of extinction affecting each region, with N_H varying by about an order of magnitude between the central and the outer parts of the diffuse emission. The variation in temperature is less certain given the associated errors. However, the presence of a $\sim 0.9 \text{ keV}$ highly absorbed plasma has been well established by *ASCA* observations (see section 5). So the correlation of higher temperatures with higher N_H supports this result. Further more, we also extracted a spectrum from a smaller ($r = 10$ pixels, $\sim 3 \text{ kpc}$) circular region which is not shown in Figure 8. The fit to the data (using the same model as for the other regions) gives $N_H = 11^{+6}_{-3} \times 10^{21} \text{ cm}^{-2}$ and $kT = 0.9^{+0.2}_{-0.3} \text{ keV}$ for the column and temperature of the thermal plasma, respectively. The large errors reflect

Figure 8. Left: Smoothed X-ray image in the 0.3-1.5 keV energy range showing the regions defined for the spatially resolved study of the diffuse emission. The radii of the regions correspond to $\sim 4, 6$, and 11 kpc. Right: Spectra of the three regions in the 0.5-10 keV energy range.

Table 7. Best-fit model parameters for the total emission in the 0.5-10 keV energy range. Solar abundances were assumed for the Mekal components. Intervening hydrogen columns are in units of 10^{21} cm^{-2} and plasma temperatures are in units of keV. *Gal* stands for a foreground Galactic hydrogen column ($9 \times 10^{20} \text{ cm}^{-2}$). Errors correspond to 90% CL for one parameter of interest. *Observed* fluxes are in units of $10^{-13} \text{ ergs s}^{-1} \text{ cm}^{-2}$ and *intrinsic* luminosities are in units of $10^{41} \text{ ergs s}^{-1}$ (for an assumed distance of 56 Mpc).

†: Same hydrogen column as applied to previous spectral component.

* Model component normalizations: 1.3×10^{-4} and 5.8×10^{-4} for the 0.6 and 0.9 keV Mekal components respectively, in units of $(10^{-14}/(4\pi D)) \times \int n_e^2 dV$ (where D is the distance to NGC3256 in cm, n_e is the electron density in cm^{-3} , and V is the volume of the emitting region in cm^3); 1.8×10^{-4} for the Power Law, in units of $10^{-4} \text{ photons cm}^{-2} \text{ s}^{-1} \text{ keV}^{-1}$.

Table 6. Best fit parameters for the diffuse emission from regions A, B and C. A M+PL model was used with each component being absorbed by an independent N_H . The power law component was frozen to a value of 2.7. Hydrogen columns are given in units of 10^{21} cm^{-2} and plasma temperatures in units of keV. The errors correspond to 90% CL for 1 parameter of interest. *Observed* (ie, uncorrected) fluxes in the 0.5-10 keV for the thermal component only are given in units of $10^{-14} \text{ ergs s}^{-1} \text{ cm}^{-2}$.

Reg	N_H	kT	N_H	Γ	$\chi^2_{\text{red}}(\text{dof})$	F_x
A	$7.7^{+2.2}_{-2.4}$	$0.76^{+0.10}_{-0.16}$	$2.3^{+0.7}_{-0.6}$	2.7	1.08(29)	8.95
B	$2.8^{+1.5}_{-1.4}$	$0.60^{+0.05}_{-0.09}$	$4.3^{+1.6}_{-0.9}$	2.7	1.14(30)	8.61
C	<i>Gal</i>	$0.63^{+0.04}_{-0.04}$	$3.6^{+2.1}_{-0.9}$	2.7	1.18(34)	10.25

the poor statistics (only 13 bins were obtained; $\chi^2_{\text{red}} = 0.9$) but it again supports the trend found in Table 6.

The quantitative results presented in Table 6 should be treated with caution. For example, the derived 0.5-10 keV flux for the central region (A) accounts for less than half of the flux determined for the 0.9 keV component (see Table 5),

which is thought to dominate in this region. The use of over-simplified and poorly constrained models to characterise the different emitting regions is probably responsible for part of the disagreement. However, it is also clear that the two thermal components observed in the integrated spectrum of the diffuse emission are not representative of the spectral complexity present on small scales; they only characterise the average properties of the emission. It is not possible to explore these important issues further with the present data, but a significantly longer exposure would no doubt answer some of the open questions.

5 COMPARISON WITH ASCA OBSERVATIONS

MLH have reported *ASCA* observations of NGC3256 and determined a total luminosity for the system of $\sim 1.6 \times 10^{42} \text{ ergs s}^{-1}$ in the 0.5-10 keV energy range. In comparison, Tables 2 and 3 imply a total luminosity of $\sim 9 \times 10^{41} \text{ ergs s}^{-1}$ in the same spectral range as determined with *Chandra*, ie, a reduction of $\sim 40\%$ in luminosity. We should attempt to understand the origin of this difference.

Given the extremely low spatial resolution of the *ASCA* (PSF FWHMS ~ 3 arcmin), the spectral analysis presented by MLH corresponds to the integrated emission (ie, diffuse plus compact sources) of most of the galaxy. Their adopted model consists of two thermal plasmas ($kT \sim 0.3, 0.8$ keV) and a power law with photon index ~ 1.7 . The power law and the high temperature thermal component are affected by a single absorbing column of $\sim 8 \times 10^{21} \text{ cm}^{-2}$. This model, however, is not a good description of a *Chandra* spectrum obtained from the total emission observed within the central 40 arcseconds of the galaxy. A model using the best fit values derived by MLH gives an unacceptable fit ($\chi^2_{\text{red}} = 1.7$). In fact, if the parameters are allowed to vary (and a Mekal component is used to described the thermal emission instead of a Raymond-Smith plasma, as used by MLH), the best fit values for the *Chandra* ‘total spectrum’ are very similar to those found for the diffuse emission only (compare Table 4 and Table 7), although a flatter power law is determined for the total spectrum, as expected from the hard spectrum that characterizes the discrete sources. From this fit we derive an *observed* flux of $\sim 1.2 \times 10^{-12} \text{ ergs s}^{-1} \text{ cm}^{-2}$ in the 0.5-10 keV energy band, which differs only by $\sim 5\%$ from the flux derived from the *ASCA* observations.

The difference in the models adopted in the analysis of the *ASCA* and *Chandra* data can explain the different derived *intrinsic* fluxes and luminosities. The change is primarily due to the reduction in the intrinsic emission (or component normalization) of the warm, 0.8-0.9 keV component, as seen by *Chandra*, which is the most luminous component in the model derived by MLH. Inspection of Figure 7b in MLH, clearly shows a warm component which is dominant in the 1-2 keV range, since the contribution from a heavily absorbed power law component is almost negligible at these energies. The *Chandra* data, on the other hand, is consistent with a less absorbed and stronger power law component, implying a smaller contribution from the warm thermal component to the overall emission.

6 DISCUSSION

6.1 The double nuclei

6.1.1 Optical, IR and X-ray properties

Optical and near-IR observations show that the properties of the northern nucleus of NGC3256 correspond to those of a strong starburst. L  pari et al (2000) found that the optical emission line features correspond to ‘those of low-ionization and high metallicity giant HII regions’. On the other hand, the outer regions ($R > 10$ arcsec) are characterised by shock excitation (L  pari et al 2000; MLH). L  pari et al also presented UV spectra of the central region (10×20 arcsec) showing strong absorption lines, implying the presence of massive young stars. Kotilainen et al (1996) obtained near-IR emission line maps of the centre of the galaxy and determined an extinction towards the northern nucleus of $A_V \sim 2.4$ magnitudes.

The southern nucleus of NGC3256 was first imaged in the near-IR continuum by Moorwood & Oliva (1994), although near-IR spectroscopy of the source had already been presented by Doyon, Joseph & Wright (1994). From their K band imaging Moorwood & Oliva detected an obscured

source located 5 arcsec to the south of the central peak (the northern nucleus) and suggested that this secondary peak corresponded to the nucleus of the merging companion galaxy. Support came with radio observations reported by Norris & Forbes (1995) showing two equally bright knots of emission. Near-IR observations by Kotilainen et al (1996) showed that the luminosity of both nuclei is comparable in the L ($3.5 \mu\text{m}$) band and they estimated an extinction towards the southern nucleus of $A_V \sim 10$ magnitudes. High resolution N-band ($12 \mu\text{m}$) images show, however, that the northern nucleus is ~ 20 times brighter than the southern peak in the mid-IR, suggesting that the northern nucleus is the dominant star-forming region in the galaxy (Lira & Ward 2002).

In order to improve the reddening estimations towards the galaxy nuclei, we have analysed archive *NICMOS* data of the central region of NGC3256. These observations were obtained on the 28th of November 1997 using the NIC2 camera (FOV = 19.2×19.2 arcsec, FWHM for a point source ~ 0.15 arcsec) and the F222M (\sim K band), F160W (\sim H band), and F190N (Pa α plus continuum at $1.90 \mu\text{m}$) filters. For details of the reduction procedure see Alonso-Herrero et al (2000). Gaussian fitting to the K-band data shows that both nuclei are resolved, with the northern nucleus (deconvolved FWHM ~ 0.25 arcsec) being more compact than the southern nucleus (deconvolved FWHM ~ 0.34 arcsec). Using an aperture of 0.76 arcsec in diameter we measured an $H - K$ colour of 0.64 magnitudes for the northern nucleus and 1.44 magnitudes for the southern nucleus. Assuming a intrinsic colour $H - K \sim 0.22$ for the nuclei of starburst and Seyfert galaxies (Glass & Morwood 1985) and the extinction law of Cardelli, Clayton & Mathis (1989) this implies a visual extinction of ~ 5.5 and ~ 16 magnitudes for the northern and southern nuclei respectively. Assuming a Galactic gas-to-dust ratio, these values of A_V correspond to a hydrogen column density for the northern nucleus of $\sim 8 \times 10^{21} \text{ cm}^{-2}$ and $\sim 2.5 \times 10^{22} \text{ cm}^{-2}$ for the southern nucleus, in good agreement with the values inferred from the X-ray observations.

The northern nucleus is the brightest X-ray source in NGC3256 with an unabsorbed luminosity of $\sim 8 - 10 \times 10^{40} \text{ ergs s}^{-1}$ in the 0.5-10 keV energy range (see Table 2). The source is clearly resolved, and therefore it probably corresponds to a compact grouping of individual sources and diffuse emission at the heart of the nuclear starburst. The deconvolved FWHM of the radial profile in the 2-5 keV range shown in Figure 2 corresponds to ~ 1 arcsec, or ~ 270 pc at the distance of NGC3256. The full band, 0.5-10 keV profile has a deconvolved FWHM of ~ 1.5 arcsec, corresponding to 400 pc, which is only a factor ~ 1.5 times smaller than the central starbursting region present in M82. The X-ray luminosity of both regions are also similar. In the case of M82 the 2-10 keV emission is dominated by a highly variable and extremely luminous point source (Kaaret et al 2001, Ward et al 2001).

The *NICMOS* data for NGC3256 do not show conspicuous sources within a radius of 1.5 arcsec of the northern nucleus. The FWHM of the peak is only ~ 0.25 arcsecs or ~ 70 pc. Although there is little evidence for a one-to-one correlation between X-ray and IR point sources, we would expect the overall size of these regions to be similar (eg, M82 - Griffiths et al 2000). Therefore any population

Figure 9. Absorption corrected fluxes for the northern nucleus (open circles) and southern nucleus (filled circles). Radio and IR data from Norris & Forbes (1995), Lira & Ward (2002), and Kotilainen et al (1996); X-ray data from this paper. *NICMOS* HK observations (this paper) are shown with smaller size symbols. The data are compared with the spectral energy distributions of radio loud and radio quiet classical quasars (dotted lines), low-luminosity AGN (dashed line) and starburst galaxies (solid line). All distributions have been normalized to the nuclear fluxes in the L ($3.5 \mu\text{m}$) band.

of X-ray emitting discrete sources (accreting binaries and compact SNRs) should be mainly associated with the very compact peak seen in the *NICMOS* data. It seems unlikely that a population of ‘normal’ binaries and SNRs could explain the observed X-ray emission, since several hundreds such sources would need to be packed within a very small volume. A more plausible scenario is that the X-ray emission is dominated by a diffuse component (eg, the base of the galactic wind - support for this scenario comes from the rather steep index of the power-law component determined in Table 2 which can also be fitted by a hot gas component with $kT \sim 2 \text{ keV}$), and/or by a few nuclear ultraluminous sources.

6.1.2 A hidden AGN?

Many authors have searched for evidence of a hidden AGN in the heavily obscured southern nucleus of NGC3256. An active nucleus could play an important role in the energetics of the galaxy. So far observations at IR and radio wavelengths have failed to provide unambiguous evidence for the presence of an AGN (Kotilainen et al, 1996; Norris & Forbes, 1995). Mid-IR *ISO* spectroscopy of NGC3256 (Rigopoulou et al, 2000) also failed to detect the high-excitation emission lines indicative of the presence of an AGN. The large aperture of *ISO* may have completely diluted the emission from a hidden active nucleus, but even if this is the case it would imply an intrinsically weak AGN which would not make a significant contribution to the total emission from the galaxy.

Our detection of the southern nucleus in X-rays allows us to address the AGN hypothesis from a different perspec-

tive. The unresolved nature of the source lends some support to the AGN scenario, although the small number of counts, coupled with the strong absorption, could conspire to hide any signature of an extended component. Adopting a power law spectral model with $\Gamma = 2.0$ and an absorbing column of $5 \times 10^{22} \text{ cm}^{-2}$ we have determined an unabsorbed X-ray luminosity for the southern nucleus of $\sim 3 \times 10^{40} \text{ ergs s}^{-1}$ in the 0.5-10 keV energy range (see Table 3). This is at least 2 orders of magnitude below the luminosities of ‘classical’ Seyfert nuclei (see for example George et al 1998). To suppress the emission from such an active nucleus requires a much higher column than the one derived from either the *Chandra* or the *NICMOS* observations.

Alternatively, the observed X-rays could correspond to scattered emission from a Compton-thick Seyfert 2 nucleus. In this case the direct emission from the primary source is suppressed by an extremely large intervening column ($N_H > 10^{24} \text{ cm}^{-2}$) which is optically thick due to photoelectric absorption (below $\sim 10 \text{ keV}$) and Compton scattered above $\sim 10 \text{ keV}$. In these objects the central source can only be seen as a reflection component which, depending on the geometry and the physical conditions around the nucleus, can originate in either the torus (which is also probably responsible for the obscuration of the primary source) or a surrounding ionized medium.

However, one of the strongest indications of reprocessed X-ray emission in Compton-thick Seyferts is the presence of an iron line with an equivalent width $> 1 \text{ keV}$ at energies between 6 and 7 keV, depending on the ionization state of the scattering material (Matt et al, 2000; Maiolino et al, 1998). The large equivalent width is a consequence of the continuum being largely suppressed. We have examined

Figure 10. X-ray isocontours overlaid onto optical HST PC2 images of the central region in NGC3256. A broad band F814W ($\sim I$) image is showed in the top panel and a colour F450W-F814W ($\sim B - I$) image is showed at the bottom (darker corresponds to redder colours - for a colour version see Figure 2 in Zepf et al 1999). Both images have the same size and (non-standard) orientation. Compact sources are labelled and the position of the southern nucleus is marked with an asterisk in the top image.

the *Chandra* data around the position of the southern nucleus and found *no* counts in the 6 to 7 keV energy band, making the scattering scenario unlikely. Finally, recent high-resolution N-band observations of NGC3256 (Lira & Ward 2002) show a weak source (~ 50 mJy) coincident with the southern nucleus. Its low luminosity is a strong argument against reprocessing and the presence of a dust enshrouded AGN.

6.1.3 A low luminosity AGN?

The presence of a low luminosity AGN (LLAGN) similar to the one observed in NGC3031 ($L_x \sim 2 \times 10^{40}$ ergs s $^{-1}$ in the 2-10 keV band, Ishisaki et al 1996) is still plausible, although this possibility would not have a significant impact on the overall energy output of the galaxy. The derived luminosity for the southern nucleus lies at the lower end of the range of luminosities determined by Ptak et al (1999) for a sample of LLAGNs and LINERs, and somewhat larger than the absorption corrected luminosity that Iwasawa et al (2000) determined for the dwarf Seyfert 1 nucleus in NGC4395.

To address this scenario we have plotted the extinction corrected emission from the nuclei of NGC3256 along with the spectral energy distributions (SEDs) of classical radio loud and radio quiet quasars (from Elvis et al, 1994), LLAGN (adapted from Ho 1999) and starburst nuclei (from Schmitt et al 1997) - see Figure 9. All the SEDs have been normalized to the observed nuclear flux in the L band. The nuclear data correspond to radio observations published by Norris & Forbes (1995), JHKL observations reported by Kotilainen et al (1996), HK *NICMOS* observations reported in this paper and N-band observations by Lira & Ward (2002). Figure 9 shows that both nuclei are too X-ray weak to be an AGN, while the radio emission has an intermediate value between the radio loud AGN and LLAGN, and the radio quiet AGN. The southern nucleus, however, shows a flat distribution between 1 and 10 μ m in νF_ν space, which is characteristic of AGN. Given the large uncertainties in the determination of the X-ray luminosity for this nucleus, the presence of a LLAGN is certainly possible. The northern nucleus, on the other hand, presents a sharp rise towards longer wavelengths, in good agreement with the spectral distribution for starburst galaxies.

For a brief discussion of the possibility that Inverse Compton scattering plays a significant role in the X-ray emission from the nuclei, see section 6.3.4.

6.2 The discrete source population

We have used archival HST observations of NGC3256 in order to search for optical counterparts of the X-ray sources seen in Figure 1. The galaxy was imaged with the WFPC2

Figure 11. Luminosity distribution of the point source population in NGC3256 (solid colour) compared with the observed (thin dotted line) and binned (thick dashed-dotted line) population seen in the Antennae galaxy (Fabbiano, Zezas & Murray, et al 2001). See text for details.

camera on board HST on the 20 of May 1994 and the 6 of September 1994, using the F450W ($\sim B$) and F814W ($\sim I$) broad band filters. The data have already been reported by Zepf et al (1999).

Figure 10 shows 0.3-10 keV X-ray iso-contours overlaid onto the HST F814W observations and an F450W-F814W colour map. The *Chandra* data have been smoothed using an adaptive smoothing technique developed by Ebeling, White and Rangarajan (1999) and implemented in the CIAO software. The algorithm uses a circular Gaussian with variable width which is adjusted in order to preserve the signal-to-noise ratio under the kernel.

Several coincidences between X-ray sources and optical knots of emission can be seen in Figure 10. In the nuclear region tentative counterparts can be found for most of the X-ray sources, and in particular for sources 5, 7(N), 9, 10 and 11, which correspond to moderately absorbed sources, as can be seen in Table 3. On the other hand, those sources with significantly large values of N_H (sources 2, 3 and 8) have no clear optical counterparts. The location of these absorbed sources in the F450W-F814W colour image shows a clear correlation between large X-ray hydrogen columns and the presence of prominent dust lanes.

Photometric measurements for the optical counterparts to the less obscured X-ray sources show that they are all characterized by blue colours, with F450W-F814W ~ -0.7 to -1.4 mags. Using the Space Telescope Data Analysis System (STSDAS) Synphot task we have also computed the F450W-F814W colour of the Orion star forming nebula and found that it is necessary to introduce a visual extinction of ~ 2.5 magnitudes to its spectral energy distribution in order to reproduce the range of colours of the star forming regions in NGC3256. From the study of the colour-colour diagram presented in section 3.2, we have derived typical absorption columns towards these sources of a few times 10^{21} cm $^{-2}$. Assuming a Galactic gas-to-dust ratio this absorption corresponds to a visual extinction of $\sim 1 - 3$ magnitudes.

Lípari et al (2000) have obtained optical spectra for several sources in the nuclear region of NGC3256. Their Region 1 corresponds to the northern nucleus, while Regions

2, 4, 5, 8 and 9 are probably the counterparts of the X-ray sources 10, 11, 13, 9 and 6 respectively (from comparison of their Figure 1c with our H α maps discussed in section 6.3.1). They found that all spectra are typical of high metallicity HII regions or starbursts with an extinction of A_V 2, in good agreement with our results from the *Chandra* observations and the HST photometry.

We have found a clear correlation between powerful and compact X-ray sources and regions of vigorous star formation. A few of the sources are clearly resolved in the *Chandra* data and probably correspond to complex regions of multiple individual sources and diffuse emission similar to a down-scaled version of the nuclear region of M82.

Most of the discrete sources seen in the *Chandra* data are unresolved. The *Chandra* spatial resolution (FWHM ~ 0.5 arcsec) implies that these point-like sources have linear sizes of 140 pc, only a factor of two smaller than the complex X-ray emitting region seen in 30 Dor, the giant HII nebula in the LMC (Wang 1999). Therefore groupings of less luminous objects contributing to many of these unresolved sources is likely.

Recent work by Helfand & Moran (2001), shows that the hard emission in NGC3256 can be explained if luminous high mass X-ray binaries, like the ones observed in the Magellanic Clouds, are representative of the source population. The 2-10 keV X-ray luminosity from all high mass X-ray binaries in the LMC or SMC is however, only $\sim 3.5 \times 10^{38}$ ergs s^{-1} (Helfand & Moran 2001), at least one order of magnitude below the average luminosity of the point sources seen in NGC3256 (for $\Gamma = 2$, approximately half of the unabsorbed luminosity will emerge in the 2-10 keV energy range - see Table 3). This implies that at least 10, and up to 30 high mass X-ray binaries ($L_x \times 10^{38}$ ergs s^{-1}) need to be clustered in a region half the size of 30 Dor. This might suggest the presence of intrinsically luminous X-ray sources in some of the discrete sources observed in NGC3256, which would dominate their X-ray output, as is observed, for example, in the M82 starburst galaxy (Griffiths et al 2000, Kaaret et al 2001, Ward et al 2001).

The presence of these point-like and highly luminous sources in selected nearby galaxies has been recognised for at least a decade (Fabbiano 1989), although only recently has the full scope of this phenomenon emerged from detailed galaxy surveys using high-resolution X-ray observations (Roberts & Warwick 2000; Lira, Lawrence & Johnson, 2000; Colbert & Mushotzky, 1999). The nature of these so called Super Eddington sources (with L_x well above the Eddington limit for a $\sim 1M$ accreting neutron star) is still poorly understood. Candidates to explain them include young supernova remnants evolving in high dense environments, accretion onto intermediate-mass black holes, mildly beamed (but otherwise normal) X-ray binaries, ‘hypernova remnants’ (ie the remnants of a Gamma-ray burst), and compact complexes of several less luminous X-ray sources. It is quite possible that the Super Eddington sources cannot be grouped into a single type of object but represent an heterogeneous class.

Chandra observations of the archetypical starburst galaxy M82 have revealed a highly variable and extremely luminous source ($1 - 10 \times 10^{40}$ ergs s^{-1}) which could imply the presence of a 500 M_\odot compact accreting object (Kaaret et al 2001). Similar massive accreting black holes

Table 8. Properties of the starbursts in NGC3256 and the Antennae galaxy. References: (1) Hummel & van der Hulst 1986, (2) Stanford et al 1990, (3) Neff & Ulvestad 2000, (4) Norris & Forbes 1995, (5) Heckman, Armus & Miley 1990. IR luminosities were obtained using IRAS fluxes (eg, Helou et al 1988) and a distance to the Antennae of 29 Mpc.

	L_{6cm} (ergs s^{-1})	L_{IR} (L)	SFR ($M_\odot yr^{-1}$)	Refs
Antennae	$\sim 1 \times 10^{39}$	$\sim 6 \times 10^{10}$	5-6	1,2,3
NGC3256	$\sim 5 \times 10^{39}$	$\sim 6 \times 10^{11}$	40-80	4,5

could explain some of the Super Eddington sources found in NGC3256. Unfortunately, the lack of significant time variability in the compact source light curves (Figure 5) means that we cannot constrain the luminosity of individual sources. However, no very short time scale variability has been detected in the luminous source in M82 suggesting that the dramatic changes in flux are not flares of short duration (Kaaret et al 2001, Ward et al 2001). The same situation is found for the Super Eddington sources detected in the Antennae galaxy (Zezas et al 2001).

The distribution of observed luminosities of the NGC3256 point source population is presented as a histogram in Figure 11 (ie, after discarding the extended sources 2, 9, 10 and both nuclei). Data from *Chandra* observations of the Antennae galaxy have also been included (Zezas et al 2001, Fabbiano et al 2001). The Antennae is the nearest example of a major merger and shows signatures of powerful star formation activity in both nuclei and throughout the colliding disks. The emission from the galaxy is dominated by the starbursts, although not as powerful as that in NGC3256 (see Table 8).

A total of 42 point sources have been detected in the Antennae and their observed luminosity distribution is plotted with a thin dotted line in Figure 11. The observations of this system have a much higher sensitivity threshold than the observations of NGC3256 and the population of point sources has been detected down to luminosities $\sim 10^{37}$ ergs s^{-1} . The central regions of this merger are affected by significant reddening (Mengel et al 2001) and the distribution of absorbing columns affecting the sources seen in the Antennae is similar to that found for NGC3256 (Zezas et al 2001), making the comparison between both galaxies clearly appropriate.

The distance to the Antennae is 29 Mpc - about half the distance to NGC3256 - and so the different physical sizes of the X-ray emitting regions probed in both galaxies can introduce significant differences in the inferred luminosity distribution of the source population. Hence, to perform a meaningful comparison of the sources seen in both galaxies we have degraded the resolution of the *Chandra* observations of the Antennae to that of NGC3256. The results are plotted in Figure 11 with a thick dash-dotted line. Only 28 point sources are found with luminosities between $\sim 10^{38} - 10^{40}$ ergs s^{-1} .

The luminosity distribution of sources seen in the Antennae and NGC3256 are very similar for luminosities above $\sim 5 \times 10^{39}$ ergs s^{-1} , but there is a clear deficiency of sources in NGC3256 below that luminosity, probably due

to the lower sensitivity of the observations. The difference between the unbinned and binned data for the Antennae suggests that some of the very luminous sources observed in NGC3256 could be composed of several less luminous components, as already suggested. This redistribution of sources would significantly populate the left hand side of the histogram and also modify its high luminosity end. Nevertheless, the existence of Super Eddington sources remains a strong possibility for NGC3256.

6.3 The origin of the X-ray emission

6.3.1 Correlation with H α emission

In order to further investigate the morphology of the diffuse component in NGC3256 we subtracted circular regions with a radius of 3 arcsec (which encircles $\sim 90\%$ of the incident photons) on a full band (0.3-10 keV) image of the galaxy at the positions of the detected discrete sources to remove their emission. We then interpolated over the holes and smoothed the image with a Gaussian with $\sigma = 1$ arcsec, obtaining a diffuse component map. Subtracting this frame of the diffuse emission from the original image we obtained an image of the population of compact sources only. This compact source map was then slightly smoothed ($\sigma = 1$ arcsec).

The two X-ray images were then compared with an archive H α observation of the galaxy obtained with the New Technology Telescope at La Silla in April 1993. The H α and associated calibration frames were reduced in the standard manner. The final H α image was obtained by scaling the ‘line’ and ‘continuum’ images until a good subtraction of the field stars was achieved.

Figure 12 shows the X-ray contours of the diffuse and discrete source population overlaid onto the H α image of NGC3256 (the ‘roundness’ of the contours representing each compact source is an artifact resulting from the smoothing of the image using a Gaussian profile). In general, there is a good agreement between the morphology seen in both wavebands. The most prominent regions seen in H α are nearly always coincident with enhanced regions of diffuse X-ray emission. Also, several X-ray compact sources are coincident with strong H α knots. One interesting feature corresponds to the H α emission coincident with source 10, where a bubble like morphology can be seen. On the other hand, no strong H α emission is detected at the position of the southern ‘Arm’ seen in diffuse X-rays. Also, none of the compact sources located in this region (sources 2, 3 and 8) have obvious counterparts in the H α image. As mentioned in section 6.1, H , K and Pa α observations of NGC3256 were obtained with *NICMOS*. The small field of view of the NIC2 camera was centered around the most obscured part of the galaxy and contained sources 7, 8, 2 and 3. Again, no counterparts were found for sources 2 and 3 in any of the *NICMOS* images, ruling out a direct association with powerful HII regions or a young dusty stellar cluster.

A crude flux calibration of the H α image can be achieved using the long slit observations reported by L  pari et al (2000). They obtained H α fluxes for the brightest knots of emission within the central region of the galaxy through a slit width of 1.5 – 2.0 arcsecs. Inspection of the H α image shows that these apertures contain the bulk of the emission for those knots used in the calibration. The spectropho-

tometric fluxes were compared with the background subtracted counts obtained from the H α image using a 2 arcsec circular aperture, giving consistent flux-to-count ratios within a factor of two. Using a large circular aperture (~ 41 arcsec in diameter) we find that the total H α flux detected in the NTT image corresponds to $\sim 2 \times 10^{-11}$ ergs s $^{-1}$ cm $^{-2}$, or $\sim 7.5 \times 10^{42}$ ergs s $^{-1}$. The H α luminosity is therefore ~ 300 times less than the IR luminosity of the galaxy. Moorwood & Oliva (1994) estimated that $L_{IR}/H\alpha \sim 175$ after correcting for absorption, and showed that this value agrees well with models of star formation in galaxies.

The H α morphology, particularly in the less reddened regions of the galaxy, is a good indicator of the most active star forming regions. In particular the good agreement seen between several compact sources detected both in X-rays and H α is a good indicator of the presence of young supernova remnants or rich associations of massive OB stars, and therefore high-mass X-ray binaries.

6.3.2 The thermal components

At least two thermal components are necessary to fit the Chandra spectrum of the diffuse emission in NGC3256. The thermal energy associated with a thermal plasma can be expressed as $E_x = 3n_e V f kT$. The electron density, n_e , can be derived from the emission integral (EI), which is given by the component normalization during the fit to the X-ray data. Assuming a purely ionised hydrogen gas, $EI = f n_e^2 V$, where f is the filling factor, or fraction of the volume V occupied by the X-ray emitting gas. If this emission is indeed powered by the starburst activity in the galaxy then E_x should be no larger than the amount of energy that the starburst has injected into the interstellar medium. This comparison assumes that the injected mass and energy, in the form of stellar winds and SN ejecta, has been efficiently thermalised to a characteristic temperature T , and evolved into a galactic wind.

MLH have already shown that the thermal energy stored in the X-ray emitting gas in NGC3256 is consistent with the amount of energy injected by the starburst in the last $\sim 10^7$ yr (\sim few 10^{57} ergs). The spectral parameters derived from our Chandra observations for the two thermal components are different from those derived from the *ASCA* data (in terms of best fitted temperatures and normalizations - see last entry in Table 4), but these differences would only amount to an increase of $\sim 30\%$ in our estimate of the total E_x (by considering both the cool and warm components). This relatively small change is due to the opposite effects introduced by the higher temperature we find for the cooler component (0.6 keV instead of the 0.3 keV derived from the *ASCA* data) and the lower normalization we determine for the warm component (~ 2.7 times smaller than the one derived by MLH). Still, a larger difference could be introduced if different geometries are assumed for the regions occupied by the plasma.

In principle, from the spatially resolved spectroscopy, we could constrain the characteristic sizes of the regions occupied by the thermal emission, in particular the volume V occupied by the warm component which was unconstrained by the *ASCA* observations (MLH assumed a spherical geometry with $r = 1.4$ kpc centered around the northern nu-

Figure 12. Diffuse (left) and discrete source population (right) X-ray contours in the 0.3-10 keV energy range overlaid onto an archive H α image of NGC3256.

cleus). Our tentative results show that the 0.6 keV component dominates for $r < 4$ kpc whilst the 0.9 keV gas dominates over $r > 4$ kpc, with an intermediate ~ 0.8 keV temperature found in between. The results are less certain if more realistic errors are computed using 2 parameters of interest for a 90% CL (ie, $\Delta\chi^2 = 4.6$): while region A is characterised by $N_H \sim 0.4 - 1.0 \text{ cm}^{-2}$ and $T \sim 0.6 - 0.9$ keV, region B is described by $N_H \sim 0.1 - 0.5 \text{ cm}^{-2}$ and $T \sim 0.5 - 0.7$ keV. As noted in section 4.2, the result on the N_H variation between the two regions is better constrained than the temperature variation.

Although not well constrained, our results suggest that the characteristic radius adopted by MLH for the spherical region occupied by the warm component could have been underestimated by about a factor two. The larger volume implies that the thermal energy stored in the 0.9 keV plasma could be as high as $\sim 1 \times 10^{57}$ ergs (for a fitted value of $EI = 1.9 \times 10^{64} \text{ cm}^{-3}$ and $f = 1$). Also, the *Chandra* data have shown that the cool component extends further than the 6 kpc radius adopted by MLH, especially towards the north-east of the galaxy (see Figure 8). The energetics in this component will be at most $\sim 1.5 \times 10^{57}$ ergs (for $r = 8$ kpc, a fitted value of $EI = 4.2 \times 10^{63} \text{ cm}^{-3}$ and $f = 1$).

The total energy stored in the thermal components is therefore in good agreement with the derived energy deposited by the starburst activity over the last $\sim 10^7$ yr. It should be remembered, however, that not all the kinetic output, in the form of star winds and supernova ejecta, is effectively thermalised in the form of a galactic wind. Although difficult to estimate, numerical simulations predict thermalisation efficiencies of 50% (Strickland 2001). If this figure is applicable to NGC3256, then only half of the energy released by the starburst (1×10^{57} ergs) would be in the form of the hot plasma observed with *Chandra*. However, taking into account that a volume filling factor close to unity for both thermal components is highly unlikely, it is still energetically possible for the starburst to power the observed X-ray emission in NGC3256.

6.3.3 The galactic wind

Although the gross properties of galactic winds are well described by theoretical models, important aspects of the nature of the X-ray emission are not understood. In particular the detailed origin of the X-rays is still an open question. In the scenario proposed by ‘mass-loading’ models the bulk of the X-rays are produced by a wind which has significantly increased its density and decreased its temperature due to heavy and efficient mixing with denser interstellar material (eg, Suchkov et al 1996). In this scenario, the physical parameters derived for the X-ray emitting material correspond to those of the wind itself. Support for the ‘mass-loading’ scenario in many galaxies comes from the comparison between the mass deposition by the starburst and the X-ray emitting mass (eg, M82 and NGC253 (Ptak et al 1997), Arp220 (Heckman et al 1996), NGC4449 (della Ceca, Griffiths & Heckman 1997), Arp299 (Heckman et al 1999)). HLM

have shown that the wind must also be heavily mass-loaded in NGC3256. On the other hand, some models postulate that the X-ray emission comes from the interaction of the hot and low density wind with clouds of gas, either ambient material that has been engulfed within the wind or that is located at the boundary layer between the flow and the surrounding medium (eg, Chevalier & Clegg 1985). In this case the tenuous wind remains largely undetectable while the X-ray emission is produced by the low volume filling factor gas from the shocked clouds. If this is the case for NGC3256, the calculations above should use $f \ll 1$ and take into account that a large fraction of the wind remains invisible in our observations. Recent *Chandra* observations of a limb-brightened outflow in NGC253 are in good agreement with the idea that the X-rays are produced in the regions of interaction between the hot wind and the denser interstellar medium (Strickland et al 2000). *XMM-Newton* observations, on the other hand, show that at lower energies the emission is more uniformly distributed, implying a higher filling factor and, probably, a ‘mass-loaded’ wind (Pietsch et al 2001).

6.3.4 The temperature gradient

Finally, our results in section 4.2 have suggested a gradient of temperature with radius. A similar distribution of temperatures has already been found in a study of the starburst galaxy M82 by Strickland, Ponman & Stevens (1997). They determined a temperature profile given by $T \propto z^{-\alpha}$, with z the distance along the minor axis of the galaxy, and $\alpha \sim 0.2 - 0.5$. Given the poorly constrained temperatures in NGC3256 only a rough profile can be derived. Adopting a characteristic temperature of 0.9 keV at the projected distance $r \sim 1$ kpc and 0.6 keV at $r \sim 6$ kpc gives a power law index $\alpha \sim 0.2$. We cannot compare this value with the ones derived for M82 or with theoretical predictions until we take into account the projection effects, ie, the superposition of different regions of the flow in our two-dimensional view of the starburst. However, the nearly spherical geometry of the wind coupled with an axis of the outflow almost coincident with the line of sight, as derived from kinematic studies (Lípari et al 2000), implies that a flux-weighted average of the temperature along the galaxy minor axis returns exactly the same power law index as the original spherical distribution: assuming that the intensity of the emission is proportional to the density squared ($I \propto \rho^2$) and that $\rho \propto R^{-\beta}$ and $T \propto R^{-\alpha}$, with R the radial distance from the centre of the starburst in spherical coordinates, it follows that

$$\frac{\int_{z=0}^{\infty} IT dz}{\int_{z=0}^{\infty} Idz} \propto \frac{1/r^{2\beta+\alpha-1}}{1/r^{2\beta-1}} \propto r^{-\alpha}$$

with $R^2 = r^2 + z^2$. In the case of M82, which is viewed nearly edge on, Strickland, Ponman & Stevens (1997) adopted a cylindrical geometry for the wind but showed that if the flow properties follow a conical or spherical geometry instead then the measured temperature profile will

be slightly flatter than the real distribution. Our result for NGC3256 is within the range of values found for M82 and is much flatter than the prediction of $\alpha = 4/3$ using adiabatic models (Chevalier & Clegg 1985). However, as explained above, the Chevalier & Clegg model postulates that the X-ray emission does not come from the wind itself, but from shocked clouds of gas. The temperature reached by these clouds will depend on the speed of the shock driven into them by the wind. A shock heated cloud model is indeed in good agreement with the results obtained for M82 (for further discussion see Strickland, Ponman & Stevens 1997).

6.3.5 The hard emission

MLH have argued that the 2-10 keV intrinsic luminosity in the power law component ($\sim 2 \times 10^{41}$ ergs s^{-1} as measured by *ASCA*) could not be explained solely by the presence of a Galactic population of high mass X-ray binaries and that Inverse Compton scattering was likely to make a significant contribution. They reached this conclusion by comparing the hard X-ray luminosity per O star observed in our Galaxy with the one inferred for NGC3256. New results published by Helfand & Moran (2001) show that in fact the 2-10 keV luminosity is well explained if a Magellanic Cloud type population of high mass X-ray binaries is assumed instead of a Galactic population.

Chandra observations show that most of the power law component seen with *ASCA* can be identified with a population of discrete sources. These extremely bright sources can have luminosities at least one order of magnitude above any source seen in our Galaxy. From a comparison of the luminosity in the discrete source population and the diffuse component in the 2.5-10 keV range we find that $\sim 75 - 80\%$ of the emission ($\sim 1.2 \times 10^{41}$ ergs s^{-1}) comes from the hard ($\Gamma \sim 2$) and powerful ($10^{39} - 10^{40}$ ergs s^{-1}) compact sources resolved by *Chandra*. A few of these sources have been found to be extended and therefore they probably correspond to compact star-forming regions. Since it is becoming increasingly evident that super Eddington sources are often found in galaxies undergoing vigorous episodes of star formation, we can speculate that some of the observed discrete sources found in NGC3256 correspond to (or are dominated by) these high luminosity sources. It is, however, impossible to test this further with the present data.

The extended emission has a power law component characterised by a fairly steep slope ($\Gamma 3$, or $kT \sim 4$ keV if a Mekal model is adopted). This component represents $\sim 75\%$ of the total luminosity in the diffuse emission in the 2.5-10 keV band (see Table 5). An image in this energy range would determine the morphology of the $\Gamma \sim 3$ emission, but our data do not have sufficient counts for this. From the spectral fit in Table 5, however, we know that a moderate extinction is associated with this component, and therefore it is unlikely that the bulk of the emission is connected with the innermost, and more heavily reddened parts of the starburst. Also, the inclusion of this component in the fit to the different spatial regions seen in Figure 8 always gave acceptable values of χ^2_{red} , suggesting that the emission is present even at large radii. Therefore, the $\sim 4 \times 10^{40}$ ergs s^{-1} emitted in the 2.5-10 keV range in the power law component

is most likely due to an unresolved population of X-ray binaries and supernova remnants distributed throughout the galactic disk. The inferred temperature is at the top end of the range of temperatures measured for young supernova remnants ($kT \sim 1 - 4$ keV; Bregman & Pildis 1992) and is close to the temperatures observed in low mass X-ray binaries ($kT \sim 3$ keV; Barret 2001). Inclusion of some contribution from the harder spectra of high-mass X-ray binaries and X-ray pulsars would improve the spectral match.

6.3.6 Inverse Compton Scattering?

Our *Chandra* observations have shown that most of the $\Gamma 2$ power law emission is accounted for by hard and powerful discrete sources. So far we have speculated that accretion onto compact objects is the dominant mechanism responsible for this emission. However, Inverse Compton (IC) scattering is also a viable non-thermal mechanism that could contribute significantly.

NGC3256 shows strong IR and nonthermal (Synchrotron) radio emission. This implies the spatial co-existence of a population of relativistic electrons and IR seed photons which could be up-scattered by the electrons into X-ray frequencies. The IC luminosity can be expressed as $L_{IC} = L_{Syn} \times U_{ph}/U_B$, where L_{Syn} is the radio luminosity and U_{ph} and U_B are the seed photon and magnetic energy densities, respectively (cf, Rybicki & Lightman 1979). The low surface brightness of the radio and IR emission outside the nuclei implies that IC emission is probably negligible in the extranuclear regions. For example, source 10 in Figure 1, the brightest source seen outside the nuclei at X-ray and optical wavelengths (for optical broad band data see Table 3 in L  p  ri et al 2000), appears much fainter than the nuclei in the L band map presented by Kotilainen et al (1996) and in the radio maps by Norris & Forbes (1995), implying a small value for the $L_{Syn} \times U_{ph}$ product.

In the case of the nuclei, however, IC emission could still play a significant role in the production of hard X-rays. This is particularly relevant in the case of the northern nucleus, which has a 2-10 luminosity of $\sim 2.5 \times 10^{40}$ ergs s^{-1} (which is completely dominated by the power law component) and has been found to be an extended source in X-rays (FWHM ~ 1 arcsec). A similar size has also been determined from radio and N-band ($12 \mu m$) observations (Norris & Forbes 1995, Lira & Ward 2002), although a much smaller peak is determined from NICMOS data at $2.2 \mu m$ (section 6.1.1). MLH have shown that between 5×10^{39} and 5×10^{40} ergs s^{-1} could be produced by IC scattering in each nucleus in the 2-10 keV band.

If IC scattering does take place, the power law spectra of the radio and X-ray emission are expected to have the same slope, since the index of the power law distribution of the electron energies (n) determines the output spectrum for Synchrotron and IC radiation in the same manner ($\alpha = (n - 1)/2$, where α is the power-law energy index of the out-coming spectra). From the radio observations of NGC3256 (Norris & Forbes 1995) we find that the power-law index of the radio emission in the nuclei has $\alpha \sim 0.8$. This value is inconsistent with the X-ray index observed in the northern nucleus power law ($\alpha = \Gamma - 1 \sim 1.2 - 2.4$ - see Table 2). More realistic errors, with 3 parameters of interest

for a 90% CL (ie, $\Delta\chi^2 = 6.3$) imply that $\alpha \sim 1 - 2.8$, with a lower limit closer to the value of the radio index. No detailed comparison can be made for the southern nucleus, although the (poorly constrained) range of power-law indices derived in section 3.2 is consistent with the observed radio slope. Therefore, IC emission cannot be dismissed as a possibly significant component of the observed hard luminosities from both nuclei, although this emission can also be explained solely by the output from accretion driven sources, and in particular, by the presence of super-Eddington sources.

7 CONCLUSIONS AND SUMMARY

Until recently, the detailed study of the diffuse emission and point source population in starburst galaxies has been a difficult task. The poor spatial resolution and limited wavelength coverage of X-ray missions prior to *Chandra* have resulted in an incomplete picture. Einstein and ROSAT images were able to detect a diffuse component and resolve some of the point sources in several starburst galaxies, but their narrow spectral energy range gave only partial information on the complex multi-components making up the emission. Satellites with wider spectral coverage (*ASCA*, *BeppoSAX*), were able to study the X-ray emission of starburst galaxies up to harder energies, but their extremely low spatial resolution gave little or no information about the different spatial components. This situation is now changing dramatically as *Chandra* data for starburst galaxies become available.

In this paper we have presented a detailed spatial and spectral analysis of *Chandra* observations of the IR luminous merger system, NGC3256. Our main results can be summarized as follows:

(1) The total absorption corrected luminosity of the galaxy over the 0.5-10 keV energy range is $L_x \sim 9 \times 10^{41}$ ergs s^{-1} ($\sim 50\%$ of the luminosity inferred from previous *ASCA* observations due to the different adopted models). A significant fraction ($\sim 80\%$) of the X-ray emission is detected as diffuse emission. Fourteen compact sources are detected, with absorption corrected luminosities between $\sim 10^{39}$ and $\sim 10^{41}$ ergs s^{-1} . The X-ray spectra of the diffuse emission is predominantly soft, while the discrete sources exhibit characteristically harder spectra.

(2) Both galaxy nuclei are clearly detected in X-rays. The northern nucleus is spatially resolved (FWHM 270 pc) and it corresponds to the brightest source, with a corrected luminosity of $\sim 1 \times 10^{41}$ ergs s^{-1} in the 0.5-10 keV range. The southern nucleus is a heavily obscured source and with an intrinsic luminosity $\sim 3 - 4 \times 10^{40}$ ergs s^{-1} . No clear evidence is found for the presence of an AGN in the southern nucleus.

(3) All the detected discrete sources have luminosities one order of magnitude above the Eddington limit for a $\sim 1M$ accreting neutron star. No doubt fainter point sources are present but are below the sensitivity threshold of our observations. No variability was detected in any of the sources found in NGC3256 and therefore, we were unable to constrain the luminosity of *individual* sources. However, intrinsically powerful sources ($L_x 10^{39}$ ergs s^{-1}) are very likely to be present.

(4) The diffuse emission has a soft spectrum which can be described as the superposition of two thermal plasma components with temperatures $T \sim 0.6, 0.9$ keV plus a

harder tail with $\Gamma \sim 3$. Tentative evidence is found from spatially resolved spectra for a trend in the extinction and the temperature of the thermal plasma to decrease with larger radial distances from the nuclear region, in agreement with observations of other starburst galaxies and with wind models.

(5) The morphology of the diffuse emission and the location of the discrete sources show a good correlation with optical and H α images. The extinction determined from the X-rays is in good agreement with the values derived from optical and infrared NICMOS data.

(6) While the thermal components in the diffuse emission can be explained in terms of the mass and energy deposition by the nuclear starburst, the observed hard tail is best explained by a combination of a population of faint point sources and hot plasma emission from young SNRs. Inverse Compton scattering could still be important in explaining the hard X-rays seen in the two nuclei.

Acknowledgements

We thank Pepi Fabbiano for kindly making available results from *Chandra* observations on the Antennae galaxy. The archival data are based on observations made with ESO Telescopes at the La Silla under programme ID 51.2-0036 and on observations made with the NASA/ESA Hubble Space Telescope, obtained from the data archive at the Space Telescope Institute. STScI is operated by the association of Universities for Research in Astronomy, Inc. under the NASA contract NAS 5-26555. This work was supported by CXC grant GO1-2116X. AZ acknowledges support by NASA contract NAS8-39073 (CXC). Data were reduced using Starlink facilities.
